ABSTRACT

Recent developments in nanoscience and nanotechnology intend novel and innovative applications in the food sector, which is rather recent compared with their use in biomedical and pharmaceutical applications. Nanostructured materials are having applications in various sectors of the food science comprising nanosensors, new packaging materials, and encapsulated food components. Nanostructured systems in food include polymeric nanoparticles, liposomes, nanoemulsions, and microemulsions. These materials enhance solubility, improve bioavailability, facilitate controlled release, and protect bioactive components during manufacture and storage. This review highlights the applications of nanostructured materials for their antimicrobial activity and possible mechanism of action against bacteria, including reactive oxygen species, membrane damage, and release of metal ions. In addition, an overview of nanostructured materials, and their current applications and future perspectives in food science are also presented.

1. Introduction

Applications of nanotechnology have been emphasized on the characterization, fabrication, and manipulation of nanostructures or nanomaterials. Nanostructured materials are those with at least one dimension falling in a nanometer scale and consist of nanoparticles (NPs), nanorods nanowires, thin films, and bulk materials made of nanoscale building blocks or consisting of nanoscale structures. Based on the dimension of their structural elements, nanostructured materials can be categorized into zero dimensional (e.g., NPs: nanoclusters, quantum dots, and fullerenes), one-dimensional (e.g.,

nanorods or nanotubes), two-dimensional (e.g., thin films), and three-dimensional (e.g., nanocomposites and dendrimers) nanomaterials.

In this review, we follow the general definition that nanotechnology is the technology dealing with both NPs and nanostructures.

Many technologies have been explored to fabricate nanostructures and nanomaterials. A nanostructure is of intermediate size between a nanodimension and a micro-dimension that can be developed as various forms. It is basically “structured” using soft/hard templates to form microlevel structures. In recent years, the definition of

1021-9498/Copyright © 2017, Food and Drug Administration, Taiwan. Published by Elsevier Taiwan LLC. This is an open access article under the CC BY-NC-ND license (<http://creativecommons.org/licenses/by-nc-nd/4.0/>).

nanostructured materials has been limited to materials that show entirely new physical and chemical properties, and therefore differ considerably from macroscaled materials with the same chemical structure [1]. Nanostructure materials are basically seen in the form of layered (lamellar) films, atomic clusters, and wire structures. Additionally, nanostructured material properties are completely dependent on the size and nature of their microstructure. The building blocks of the nanostructured materials are basically NPs, which are of the simplest form; nanocomposites are made of more complicated elementary structures.

Applications of nanotechnology in food science are going to impact the vital aspects of food and related industries from food safety to the molecular synthesis of new food products and ingredients [2]. The unique properties of these nanostructures and nanomaterials including physical, chemical, and biological properties are considerably different from their bulk counterparts alter the understanding of biological and physical occurrence in food systems. Several recent reports and reviews have identified potential applications of nanotechnology for the food sector to improve food safety, to enhance packaging and lead to improved processing and nutrition [3–10].

Increasing the shelf life of the food (preservation), food safety, coloring, flavoring, and nutritional additives, and using the antimicrobial ingredients for food packaging are some of the important applications of nanotechnology in the food industry [5,11]. Nanotechnology has major advantages in its usage for packaging in comparison with the conventional ways using polymers, which may include merits such as enhanced barrier, and mechanical and heat-resistant properties, along with biodegradability [12]. In addition to enhanced antimicrobial effects, nanomaterials can be used for detection of food spoilage through nanosensors [13].

Although nanotechnology has a great potential to fabricate innovative products and processes in the food sector, there are many challenges to overcome in food science and technology. The major challenges are to produce edible delivery systems using economic processing operations with effective formulation for human consumption and safety [14]. In this context, nanostructures are produced from food-grade ingredients using simple and economic approaches (such as the layer-by-layer technique).

This review updates current applications of nanotechnology to the food industry, presenting the use of different nanostructures and related manufacturing technologies used to build functional food systems. Moreover, this article focuses on applications particularly toward current and emerging technologies that may be used for food formulations, processing, and storage. This review also highlights the applications for antimicrobial activity and their possible mechanism of action against bacteria, including reactive oxygen species (ROS), membrane damage, and release of metal ions.

2. Methods used in nanofabrication

Top-down and bottom-up are the two approaches to the synthesis of nanomaterials and fabrication of nanostructures.

The top-down approach is to break bulk materials using milling to reduce the size to nanoscale. It involves mechanical grinding of bulk materials and subsequent stabilization of the resulting nanosized particles by the addition of colloidal protecting agents. However, the major problem with the top-down method is the slow production rate, which makes it unsuitable for mass production [15,16]. The other disadvantages include surface defects (i.e., imperfections), contaminations, and introduction of internal stress. This process also involves material wastage and is limited by the resolution of the tools employed.

The bottom-up approach is fundamentally different from the top-down approach, involving the building of nanomaterials from individual atoms that have the ability to self-assemble in a natural and self-regulating manner [17]. The bottom-up approach has a better chance of producing nanostructures with less defects, more homogenous chemical composition, and better short- and long-range ordering.

3. Various processes for the structuring of food materials

The specific processes of NP preparation through the top-down approach are dry milling, high-pressure homogenization or micofluidization, and ultrasound emulsification [18]. Milling is a conventional method, where mechanical energy is applied to physically break down materials to coarse particles (size reduction to nanoscale). For example, dry milling technology can be used to obtain wheat flour of fine size that has a high water-binding capacity [19] and also to enhance the antioxidant activity in green tea powder [20]. Homogenizers have been used conventionally for reducing the size of fat globules to augment the stability of emulsions [21]. A liquid product is subjected to very high stress causing the formation of extremely fine emulsion droplets in high-pressure homogenization. High-pressure homogenizers are proficient in producing finer milk emulsions than conventional homogenizers [22]. Micofluidization is a form of homogenization in which auxiliary chambers are used for size reduction and emulsion formation, thereby it enhances texture and mouth feel [18]. It has effectively been used in the production of salad dressing, creams, yogurts, syrups, chocolate and malted drinks, flavor oil emulsions, fillings, and icings [23]. More recently, reported during the time period 2011–2016, ultrasound emulsification is used to prepare oil and water nanoemulsions using high-intensity ultrasound waves that can change the characteristics of treated matter through intensive shear forces, pressure, and temperature due to cavitation [24–26].

4. Nanostructured materials in food

Some food products contain the ingredients that are nanosized and different from synthetically manufactured nanomaterials. Many food proteins are of globular structures between 10 nm and 100 nm in size, and others include the majority of polysaccharides and lipids, which are linear polymers of <1 nm in thickness (one-dimensional

nanostructures). Milk and milk products, such as milk proteins and casein, are also natural nanostructures.

The most significant synthetic nanostructured systems in food are polymeric NPs, liposomes, nanoemulsions, and microemulsions. These materials enhance solubility, improve bioavailability, facilitate controlled release, and protect bioactive components during manufacture and storage [27]. An overview of nanostructures in food and their applications in food science are illustrated in Figure 1.

4.1. Biopolymeric nanostructured particles (proteins)

Micelles (spherical structures of 5–100 nm in diameter) are able to encapsulate nonpolar molecules such as lipids, vitamins, and antioxidants. Elements that are not water soluble can be solubilized using micelles and are referred to as microemulsions. Microemulsions have also been used to produce glycerides for applications in food products. An important application of microemulsion is to provide improved anti-oxidation effectiveness because of the possibility of a synergistic effect between hydrophilic and lipophilic antioxidants.

Food-grade biopolymers such as proteins or polysaccharides can be used to produce nanometer-sized particles [28–30]. One of the most common components of many biodegradable biopolymeric NPs is polylactic acid. It is commonly available from a number of manufacturers. Polylactic acid is regularly used to encapsulate and deliver drugs, vaccines, and proteins, but it has certain limitations: it is quickly removed from the bloodstream and remains isolated in the liver and kidneys. As its purpose as an NP is to deliver active components to other areas of the body, polylactic acid needs an associative compound such as polyethylene glycol to be successful in this regard [31].

4.2. Liposomes

Liposomes are spherical bilayered vesicles of phospholipids [32]. Liposomes have been used in the food industry to encapsulate functional ingredients, and more recently, they have been explored for their ability to integrate food antimicrobials that could aid in the protection of food products

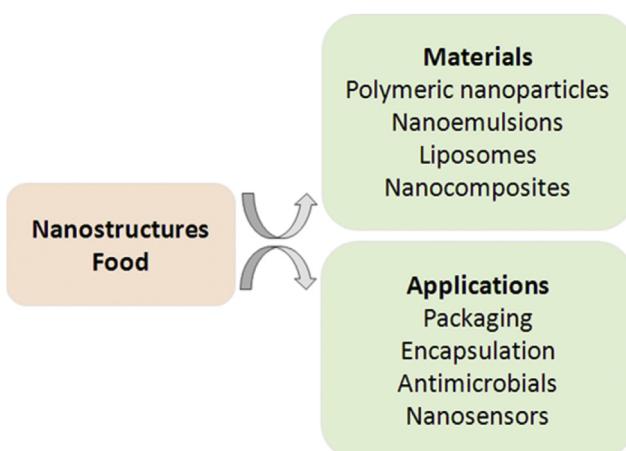

Figure 1 – Overview of nanostructures in food and their applications in food science.

against growth of spoilage and pathogenic microorganisms [33]. Lipid-based nanoencapsulation can potentially improve the solubility, stability, and bioavailability of foods, thus preventing unwanted interactions with other food components. Nanoliposomes are some of the most promising lipid-based carriers for antioxidants. Nanoliposomes also help in controlled and specific delivery of nutraceuticals, nutrients, enzymes, vitamins, antimicrobials, and additives [32]. Liposomes have a smaller size and a larger interfacial surface area for contact with biological tissues, and thereby provide greater bioavailability of encapsulated compounds [27,34,35].

4.3. Nanoemulsions

Nanoemulsions are colloidal dispersions with droplet sizes ranging from 50 nm to 1000 nm. They are used to produce food products for flavored oils, salad dressing, personalized beverages, sweeteners, and other processed foods [36]. Nanoemulsions present many advantages such as decontamination of equipment and high clarity without compromising product appearance and flavor. Nanosized functional compounds that are encapsulated by the self-assembled nanoemulsions are used for targeted delivery of lutein; β-carotene; lycopene; vitamins A, D, and E; co-enzymeQ10; and omega-3-fatty acids [37]. Stable double-layered capsaicin-loaded nanoemulsions were stabilized with natural polymers such as alginate and chitosan for use as a functional ingredient delivery system [38]. Functional food components can be integrated within the droplets [39] regularly to allow a slowdown of chemical degradation processes by engineering the properties of the interfacial layer surrounding them [40]. Another application of nanoemulsion includes bottled drinking water and milk fortified with vitamins, minerals, and antioxidants [41].

4.4. Nanocomposites

Using the polymers in nanocomposite food packaging is one of the good alternatives for conventional packaging materials (glass, paper, and metals) due to their functionality and low cost [42]. Nanocomposites are polymer matrices reinforced in the nanofillers (nanoclays, nanoxides, carbon nanotubes, and cellulose microfibrils), where one of the phases has at least one, two, or three dimensions less than 100 nm in size [43]. Several synthetic (polyamide, polystyrene, nylon, and polyolefins) and natural (chitosan, cellulose, and carrageenan) polymers have been used in food packaging [43,44]. However, due to environmental concerns, there is a growing demand for biodegradable packaging with the use of biopolymers that are either natural or synthetic (polyvinyl alcohol, polylactide, and polyglycolic acid) [45].

5. Applications of nanostructures in the food industry

Potential applications in food science and technology are mainly categorized into packaging, process technology, antimicrobials, and food ingredients. Its usage in foodstuff can be categorized as “direct” or “indirect.” Direct use refers to the

incorporation of nanostructured substances and materials in foodstuff and must also be declared as such. Some of the direct applications include fragrances, coloring agents, antioxidants, preservatives, and biologically active components (vitamins, omega-3 fatty acids, polyphenols, etc.). Indirect use comprises the use of nanostructured materials in packaging technology [13] and sensors, or the use of proficiently nanostructured catalysts for the hydration of fats [46,47]. Therefore, greater parts of applications of nanostructured materials are included in this category. However, it should be noted that indirect use of nanostructures come into contact with the foodstuff [1,48], as they are directly incorporated into matrix to benefit food production such as catalyzed hydration of fats with low trans-fatty acid contents.

5.1. Nanosensors

Nanodevices or nanosensors in conjunction with polymers are used to monitor food pathogens and chemicals during storage and transit processes in smart packaging [49,50]. Additionally, smart packaging ensures integrity of the food package and authenticity of the food product. Furthermore, these devices may also track the history of time, temperature, and expiration date. Several recent reports indicated that nanosensors are able to detect toxins and food pathogens in the packaging [43,51,52]. Nanosensors for food analysis, flavors, drinking water, and clinical diagnostics have also been developed [53], and NPs can also be incorporated as nanostructured transducers of biosensor devices [54].

A low-cost nanobioluminescent spray [55] was developed, which reacts with microbes making the food to produce a visual glow, thereby indicating microbial contamination. Nanocantilevers are used for pathogen detection, and recently a rapid biosensor (i.e., micromechanical oscillators) was developed for the detection of bacterial growth of *Escherichia coli* [56]. The basis of the detection scheme is the change in resonance frequency as a function of the increasing mass on a cantilever array, which can detect *E. coli* within 1 hour, which is considerably faster than any conventional plating method that needs at least 24 hours. Cantilevers can also be used to detect other changes such as temperature, superficial tension, and mass. Using a series of cantilevers with different molecular recognition elements together in an array mounted on a single chip can be used to detect multiple toxins and microorganisms [57,58]. Molecular imprinted polymers and nanomaterials, being developed for food quality control, are able to recognize a large number of small molecules, large proteins, and macromolecules. Recently, an imprinted core–shell NPs with a silica core has been developed for the detection of tert-butylhydroquinone in foodstuff [59]. Additional nanosensors developed based on the molecular imprinted polymer technology include those used for the detection of trypsin, glucose, catechol, and ascorbic acid [60–64].

5.2. Food packaging

Nanotechnology offers food safety in terms of packaging for ensuring a longer shelf life by avoiding spoilage or loss of food nutrients. Active packaging has a desirable role in food preservation other than providing an inert barrier to the external

conditions. It mainly refers to the packaging systems that respond to changes in the environment. They act by releasing desirable molecules such as antimicrobial or antioxidant agents, or act as gas scavengers. These interactions result in improved food stability, and some of these packaging systems include the antimicrobials, oxygen scavengers, and enzyme immobilization systems. Another application in active packaging is the controlled-release packaging, where nanocomposites can also be used as delivery systems, thereby helping the migration of functional additives, such as minerals, probiotics, and vitamins, into food [65]. Silver NPs are used in packaging materials to preserve food for longer periods by killing microorganisms in 6 minutes [18,66]. Nylon nanocomposites providing barriers to oxygen and carbon dioxide flow have also been used in food packaging to maintain freshness and block out smells in food. A typical example is multilayer polyethylene terephthalate (PET) bottles for beer and alcoholic beverages [66,67].

Active packaging includes usage of metal and metal oxide NPs as antimicrobial agents in the form of nanocomposites for food packaging. Titanium dioxide, zinc oxide, copper, copper oxide, and silver-based nanofillers are used due to their antimicrobial properties [11]. TiO₂- and SiO₂-based nanofillers are used for applications in self-cleaning surfaces [11]. Among them silver NPs are the most common NPs, which are effective against a wide variety of microorganisms [13,68]. Adhesion to cell surface, disruption of cell membrane, DNA damage, and release of silver ions are the mechanisms of silver antimicrobial agent [11,69,70]. The antibacterial activity of metal nanostructures is mostly dependent on various factors such as large surface area, size, shape, particle internalization, and chemical functionalization [71]. Our earlier studies and reports from others demonstrated that these nanostructures can penetrate into outer and inner bacterial membranes [70,72–74]. Three major mechanisms of bacterial toxicity of metal-containing nanomaterials (Figure 2) that are widely accepted in literature include metal ions uptake

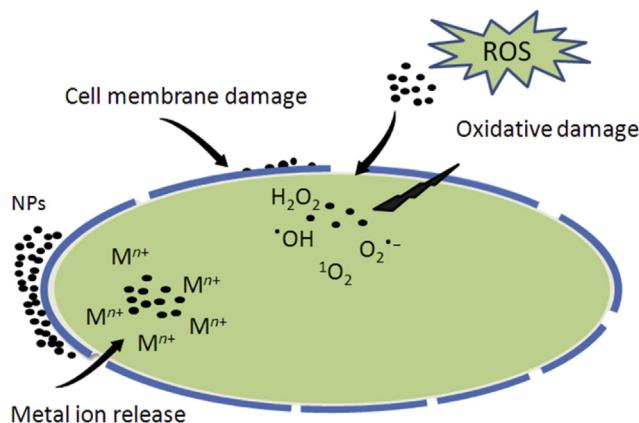

Figure 2 – Schematic representation of possible mechanisms of toxicity involved in metal-containing nanomaterials: (1) metal ion uptake into cells, (2) generation of reactive oxygen species, and (3) bacterial cell membrane damage. NP = nanoparticle; ROS = reactive oxygen species.

causing depletion of intracellular ATP [75], generation of ROS causing oxidative damage to cells [76,77], and bacterial membrane damage [78]. ROS include free radicals such as superoxide anion (O_2^{-}), hydroxyl radical ($\cdot OH$), as well as nonradical molecules such as hydrogen peroxide (H_2O_2) and singlet oxygen (1O_2) [77].

Titanium dioxide has a broad range of applications, for example, as a UV blocker, pigment, photocatalyst, and antimicrobial agent [79]. Moreover, TiO_2 NPs are effective against food spoilage-related bacteria [80,81], and they are also used in food packaging [11,79]. Besides TiO_2 , it was reported that a plastic wrap containing ZnO NPs can be used to keep packaging surfaces hygienic under indoor lighting conditions [5]. Oxygen scavenger films were developed by adding TiO_2 NPs into different polymers [82] under UV illumination, but one major drawback of TiO_2 NPs is due to its photocatalytic mechanisms, i.e., becoming active mainly under UV light because of the large bandgap [83]. The major toxicity mechanism of TiO_2 nano-materials is the production of ROS under visible and UV light (photocatalytic activity) causing lipid peroxidation, which leads to oxidative stress and cell death [74,84–86].

Graphene nanoplate-based nanocomposites are reported for their heat resistance and barrier properties, which have an improved food-packaging application [87]. Carbon nanotubes and nanofibers are used due to their electrical and mechanical properties, but their applications in food packaging are limited because of the cost factor and difficulty in processing dispersions [88]. Nanoclays with montmorillonite NPs in different starch-based materials (biodegradable polymers) were developed to improve barrier and mechanical properties [89]. Most commonly used nanoclay material montmorillonite (also known as bentonite) is used to achieve the gas barrier properties, and it can restrict permeation of gases when incorporated into a polymer. It is also widely available and is relatively inexpensive. Some of the biodegradable nanocomposites in starch clay have been reported for several applications including food packaging [90–94].

5.3. Encapsulated food components and edible supplements

The potential applications of nanotechnology in functional food, and design of nutritional supplements and nutraceuticals containing nanosized ingredients and additives such as vitamins, antimicrobials, antioxidants, and preservatives are currently available for enhanced taste, absorption, and bioavailability [95]. To avoid accumulation of cholesterol, some of the nutraceuticals incorporated in the carriers consist of lycopene, beta-carotenes, and phytosterols [96]. A green tea product containing nanoselenium has many health benefits resulting from better uptake of selenium. Nanoencapsulation is the process of packing materials at nanoscale with the help of nanocapsules, and it provides final product functionality that includes controlled release of the core. Thus, encapsulated forms of ingredients have several advantages, which include a longer shelf life, enhanced stability, consecutive delivery of multiple active ingredients, and pH-triggered controlled release. Functional ingredients such as vitamins, antioxidants, probiotics, carotenoids, preservatives, omega

fatty acids, proteins, peptides, and lipids as well as carbohydrates are incorporated into a nanodelivery system [97]. This increases the functionality and stability of these foods, as they are not used in their pure form. Lipid based nano-encapsulation can potentially improve the solubility, stability, and bioavailability of foods, thus preventing unwanted interactions with other food components. Nanoliposomes and nanocoachleates are some of the most promising lipid-based carriers for antioxidants. Nanoliposomes also help in controlled and specific delivery of nutraceuticals, nutrients, enzymes, vitamins, antimicrobials, and additives [32]. Nano-coachleates have the ability to stabilize micronutrients and can enhance the nutritional value of processed foods. Nano-encapsulated probiotics can be selectively delivered to certain parts of the gastrointestinal tract, where they have the capability to modulate immune responses [98]. In the current market, Tip-Top Up bread in Western Australia is fortified with omega-3 fatty acids, which makes it one of the best examples of the above-mentioned application. HydraCel, a natural mineral product (5 nm in size) can be used to improve the absorption of water and other nutrients in the body by decreasing the surface tension of drinking water [99]. Other nanoencapsulated products include α -lactalbumin (a hydrolyzed milk protein) as a carrier of nutrients [100], casein micelles for delivery of sensitive food products [101], dextrans for bioactive products, and hydrophobically modified starch to encapsulate curcumin [102].

6. Toxicological aspects

In contrast to the beneficial applications as antimicrobials and antioxidants, overproduction of ROS by nanostructures is expected to cause a cell-damaging effect. Overall, literature reports on the toxicity of nanostructures used in food science are very limited. The common properties shared by nanostructures and NPs, such as nanoscale, large surface area, and high reactivity, may pose a health threat to humans and other organisms. Nanostructures in the food sector may not create a direct effect on human health; however, their nanoscale property may cause some unavoidable side effects. Mechanisms of toxicity induced by nanomaterials or NPs have been studied intensively [77,103,104]. Nanotoxicity is principally mediated through the overproduction of ROS, resulting in the induction of oxidative stress and thereby resulting in cells failing to maintain normal physiological redox-regulated functions. Thus, nanotoxicity can lead to DNA damage, unregulated cell signaling, change in cell motility, cytotoxicity, apoptosis, and cancer initiation [77]. As described previously [77], the critical determinants of nanotoxicity include size, shape, particle surface, surface positive charges, surface-containing groups, particle dissolution, metal ion release from nanometals and nanometal oxides, UV light activation, aggregation, mode of interaction with cells, inflammation, and pH of the medium. As such, it is apparent that the severity of toxicity of nanomaterials should be in the following order: NPs > nanotubes (nanowires) > nanostructures. Thus, the information concerning the nanotoxicity caused by NPs can provide some useful reference for the nanostructure-induced

toxicity. Besides, these nanostructured materials or NPs used in packaging materials may migrate into food. For example, silver and zinc oxide NPs may migrate into food when they are used as packaging materials, and silver ions of a detectable level were leached into the meat exudates (although not into the meat itself) [105]; it was also reported that the metal ions of silver and zinc leached into food substance (orange juice), which may accelerate the degradation of ascorbic acid [106]. Hence, further research is needed before these antimicrobial nanocomposite packaging materials are commercialized. Other studies showed that migration of NPs into actual food occurs [107–111]. However, a recent report by ToxConsult Pty Ltd [112] indicated that based on the case studies of food packing with nanomaterials migration of intact NPs into food simulants were found to be negligible. Nevertheless, validity of the testing results may be compromised, as the complex matrix of most foods could interfere with precise measurements of migrated NPs or ions within the food [107,113]. Therefore, more studies need to be conducted to evaluate the potential toxicity of nanomaterials or nanostructures to be used in food science and related industries.

7. Future perspectives

While scientific advances in the application of nanotechnology to the food industry have been progressing rapidly, development of nanotechnology associated with nanostructures is relatively much slower. As the research in food nanotechnology increases, it also raises public concerns about safety of the products of nanotechnology for human consumption and usage [114]. Therefore, a comprehensive assessment of potential risks to human health is essential before the nano food products are commercially available. However, there has been a lack of a universal guideline that is specifically developed for the safety assessment of nanomaterials in food. Recently, EU regulations established that any food ingredient resulting from nanotechnological applications must undergo safety assessment before being approved for its use [115]. Some guidelines were also released recently from the United States Food and Drug Administration, which are related to the use of nanotechnology in food [116]. Without a doubt, in the near future more studies and regulations concerning the impacts of these nanomaterials on human and environmental health need to be conducted and established to assure our food safety.
